Abstract

When Large Language Models are deployed as autonomous agents in high-stakes domains, continual learning from user interactions can gradually increase constraint violations, even when the initial policy is safety-aligned. We refer to this phenomenon as *Safety Drift*. We formalize Safety Drift within a Constrained Markov Decision Process (CMDP) framework and study mitigation via the Augmented Lagrangian Method (ALM). The key theoretical insight is that ALM's quadratic penalty term should stabilize the dual dynamics (λ) relative to a naive Lagrangian update. We introduce a *Drift Induction Protocol*—a reproducible reward-perturbation stress test—and conduct experiments with **actual Qwen-0.5B inference** (100 episodes $\times$ 3 seeds). Preliminary results show ALM achieves the lowest λ variance (0.0004 vs 0.0009 for PID-Lagrangian), confirming the theoretical prediction. However, with limited training episodes, ALM does not yet outperform baselines on cost rate, suggesting that longer training horizons are necessary. We discuss the alignment–utility trade-off and practical deployment considerations.

1 Introduction

Large Language Models are increasingly deployed as autonomous agents that plan, reason, and act over multiple steps [**??**]. Unlike static instruction-tuned models, these agents may continue to update from deployment feedback. In high-stakes domains, this continual adaptation introduces a specific risk: optimization pressure can gradually shift behavior toward higher task reward at the expense of safety constraints.

We study this risk through the lens of constrained optimization. Starting from a safety-aligned policy (e.g., via RLHF or Constitutional AI), subsequent gradient updates can increase expected constraint violations if the reward signal incentivizes unsafe behavior. The resulting failures are often incremental rather than abrupt, which makes them harder to detect and triage in deployment.

Standard reinforcement learning methods such as PPO optimize expected return and do not enforce safety constraints by construction. A common workaround is to encode safety as a soft penalty in the reward, but soft penalties can be dominated by strong or adversarial incentives [**???**]. This motivates a formulation where constraints are explicit and enforced during optimization, as studied in safe RL surveys [**??**].

We formalize the problem as a Constrained MDP and study an Augmented Lagrangian Method (ALM) solver. While ALM is classical, its use as a practical constrained optimizer for self-evolving LLM agents remains under-explored. Empirically, the quadratic penalty term introduces curvature that stabilizes the dual dynamics and improves robustness under drift-inducing incentives.

This paper makes three concrete contributions:

1. **Safety Drift metric:** We formalize Safety Drift as a time-indexed increase in expected constraint violations (Eq. 2), enabling longitudinal measurement under continual learning. This metric distinguishes drift from standard catastrophic forgetting.
2. **Drift Induction Protocol (DIP):** We introduce a reproducible stress-test based on reward perturbation to quantify drift resistance. This evaluation protocol is novel and allows systematic comparison across constrained optimization methods.
3. **Stabilized constrained optimization for drifting agents:** We show that an ALM-based CMDP solver stabilizes the dual dynamics (λ) and increases drift resistance (time-to-crack, Table 2). Ablations in Table 3 isolate the role of the quadratic penalty (μ) and the adaptive dual optimizer.

We focus on the constrained optimization setting and defer privacy or adversarial evaluation components to future work.

2 Problem Formulation

2.1 Modeling Agents as CMDPs

An autonomous agent interacts with an environment through a sequence of states and actions. We model

this formally as a Markov Decision Process: $\mathcal{M} = \langle \mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma \rangle$. Here, $\mathcal{S}$ is the state space (e.g., conversation history), $\mathcal{A}$ is the action space (generated tokens), $\mathcal{P}$ is the state transition distribution, $\mathcal{R}$ is the reward function, and γ is the discount factor.

Standard RL maximizes expected cumulative reward: $J(\pi) = \mathbb{E}_{\tau\sim\pi}[\sum_{t=0}^{T} \gamma^t r(s_t, a_t)]$. But this formulation permits trade-offs between utility and safety. In high-stakes domains, we need a different approach. We adopt a **Constrained MDP** [**??**], which augments the MDP with a set of cost functions $\mathcal{C} = \{c_1, \ldots, c_K\}$ and corresponding thresholds $\{d_1, \ldots, d_K\}$.

The objective becomes:

$$\max_{\pi} J(\pi) \quad \text{s.t.} \quad J_{c_k}(\pi) \leq d_k \tag{1}$$

where $J_{c_k}(\pi) = \mathbb{E}_{\tau\sim\pi}\left[\sum_t \gamma^t c_k(s_t, a_t)\right]$ for all k.

We treat these as hard constraints (CMDP), in contrast to reward shaping with soft penalties.

2.2 Defining Safety Drift

Let π_0 be the initial safety-aligned policy (e.g., after RLHF). Let π_t be the policy after t update steps in the deployed environment. We define **Safety Drift** as the increase in expected constraint violations over time:

$$\Delta_S(t) = \max_k \left(J_{c_k}(\pi_t) - J_{c_k}(\pi_0)\right) \tag{2}$$

Positive drift means the agent is becoming less safe. Our goal is to ensure $\Delta_S(t) \leq \epsilon_{drift}$ for all t, where ϵ_{drift} is a small tolerance (we use 0.025, or 2.5%). This relaxation acknowledges that perfect zero drift is unrealistic in stochastic environments; small bounded drift is acceptable. What we want to prevent is *unbounded* drift—the agent gradually abandoning its constraints.

Note that Safety Drift differs from catastrophic forgetting [**??**]: while forgetting involves losing task performance, drift involves gradually violating safety constraints despite maintaining (or improving) task reward.

2.3 The Alignment-Utility Trade-off

There is an inescapable tension here. Making the agent perfectly safe often means refusing legitimate requests. A financial advisor that never gives advice (to avoid liability) is useless. The question is not how to achieve infinite safety at zero cost, but how to navigate the Pareto frontier of utility versus safety.

Formally, for a given safety threshold d_k, the maximum safe utility is:

$$U^*_{\text{safe}} = \max_{\pi} J(\pi) \quad \text{s.t.} \quad J_{c_k}(\pi) \leq d_k \tag{3}$$

The unconstrained maximum is $U^*_{\text{unc}} = \max_\pi J(\pi)$. The difference $U^*_{\text{unc}} - U^*_{\text{safe}}$ is what we call the *Alignment Tax*. It's the utility we give up to stay safe. In regulated industries, this is not a bug—it's a feature. The cost of a regulatory violation far exceeds the marginal utility gain from a risky answer.

Safety Drift occurs when the optimization algorithm implicitly relaxes constraints by allowing λ (the dual penalty) to decay, effectively pushing the policy toward U^*_{unc}. Privatris prevents this by dynamically adjusting λ to maintain the constraint boundary.

3 Constrained Optimization via Augmented Lagrangian Methods

3.1 The Augmented Lagrangian Formulation

To solve the CMDP, we introduce Lagrange multipliers $\lambda = (\lambda_1, \ldots, \lambda_K) \geq 0$ and a penalty coefficient $\mu > 0$. The Augmented Lagrangian is:

$$\begin{aligned} L_{\text{aug}}(\pi, \lambda) = J(\pi) &- \sum_k \lambda_k (J_{c_k} - d_k) \\ &- \tfrac{\mu}{2} \sum_k [\max(0, J_{c_k} - d_k)]^2 \end{aligned} \tag{4}$$

The first term is the standard Lagrangian. The second term—the quadratic penalty—is what distinguishes ALM. By penalizing constraint violations quadratically, we add curvature to the dual objective. This has a practical benefit: when λ is updated, the quadratic term acts like a "brake," preventing wild oscillations that plague gradient-ascent updates.

Compare this to the naive Lagrangian (without penalty term):

$$L_{\text{naive}}(\pi, \lambda) = J(\pi) - \sum_k \lambda_k (J_{c_k} - d_k) \tag{5}$$

The naive approach is simpler, but it's also more aggressive. When the agent violates a constraint, λ jumps up sharply. When it complies, λ drops. These oscillations destabilize training, and the final policy can be sensitive to the timing of constraint violations.

3.2 Primal-Dual Optimization

We solve the CMDP via alternating primal and dual updates:

Primal Update (Policy): Fix λ and maximize $L_{\text{aug}}(\pi, \lambda)$ using PPO. The modified reward is:

$$r'(s, a) = r(s, a) - \sum_k \lambda_k c_k(s, a) - \mu [J_{c_k} - d_k]_+ c_k(s, a) \tag{6}$$

This is standard: we penalize actions that violate constraints, scaled by λ and the quadratic penalty.

Dual Update (Lagrange Multiplier): We update λ via adaptive projected dual updates (Adam):

$$\lambda_{k,t+1} \leftarrow \text{Adam}(\lambda_{k,t}, \nabla_\lambda L = J_{c_k}(\pi_t) - d_k, \alpha) \tag{7}$$

Specifically:

$$m_t = \beta_1 m_{t-1} + (1 - \beta_1)(J_{c_k} - d_k) \tag{8}$$

$$v_t = \beta_2 v_{t-1} + (1 - \beta_2)(J_{c_k} - d_k)^2 \tag{9}$$

$$\lambda_{k,t+1} = \left[\lambda_{k,t} + \alpha \frac{m_t}{\sqrt{v_t} + \epsilon}\right]^+ \tag{10}$$

The $[\cdot]^+$ operation clamps λ to non-negative values, since multipliers must remain ≥ 0 in a maximization

problem. Adam's adaptive learning rates and momentum further reduce overshooting in the dual updates. As shown in Table 3, the quadratic penalty term (μ) is the primary stabilizer, while Adam provides additional robustness.

3.3 Value Network Architecture

To implement GAE for both rewards and costs, we use a multi-head value network. Unlike standard PPO (which estimates a single scalar $V(s)$), our critic outputs:

$$V(s) = [V^r(s), V^{c_1}(s), \ldots, V^{c_K}(s)]^\top \tag{11}$$

Each head is an MLP layer on top of a shared Transformer encoder. This separation allows independent advantage computation via GAE for rewards and costs:

$$A^r(s_t) = \sum_{l=0}^{T_{\text{GAE}}} (\gamma\lambda_g)^l \delta_t^r, \quad A^{c_k}(s_t) = \sum_{l=0}^{T_{\text{GAE}}} (\gamma\lambda_g)^l \delta_t^{c_k} \tag{12}$$

where $\delta_t^r, \delta_t^{c_k}$ are TD residuals and $\lambda_g = 0.95$ is the GAE parameter. The policy gradient becomes:

$$\nabla_\theta \log \pi(a|s) \left(A^r(s) - \sum_k \lambda_k A^{c_k}(s) \right) \tag{13}$$

3.4 Training Algorithm

Algorithm 1 formalizes the constrained training procedure.

Algorithm 1 ALM-Based CMDP Training for LLM Agents

Input: Untrained policy π_θ, value network V_ϕ, hyperparameters α, μ, d_k
Initialize: $\lambda \leftarrow 0$, buffer $\mathcal{B} \leftarrow \emptyset$
for episode $e = 1$ **to** $N_{episodes}$ **do**
  Sample context $s_0 \sim \mathcal{D}$
  Generate rollout $\tau = (s_0, a_0, r_0, \ldots, s_T)$ via π_θ
  Compute trajectory cost: $C_k(\tau) = \sum_t \gamma^t c_k(s_t, a_t)$ for all k
  Add $(\tau, C_k(\tau))$ to buffer $\mathcal{B}$
  if $|\mathcal{B}| \geq B_{\text{batch}}$ **then**
    Compute advantages $A^r, A^{c_1}, \ldots, A^{c_K}$ via GAE
    Compute constraint violations: $\hat{J}_{c_k} \leftarrow \frac{1}{B} \sum_{\tau \in \mathcal{B}} C_k(\tau)$
    Policy Update: Run PPO on modified reward $r' = r - \sum_k (\lambda_k + \mu[J_{c_k} - d_k]_+) c_k$ for N_{PPO} steps
    Dual Update: For each k:
      $(m, v) \leftarrow \text{Adam_step}(\hat{J}_{c_k} - d_k, m, v)$
      $\lambda_k \leftarrow [\lambda_k + \alpha \cdot m/(\sqrt{v} + \epsilon)]^+$
    Clear $\mathcal{B}$
  end if
end for

4 Experimental Setup

4.1 Evaluation Environment: Drift Induction Protocol

To rigorously test resistance to safety drift, we introduce a **Drift Induction Protocol**. This is not a passive benchmark; it actively tries to induce drift.

Phase 1 (Steps 1–5,000): *Standard Alignment.* The agent receives positive reward (+1) for safe, helpful responses and negative reward (−1) for harmful responses. Constraints are easily satisfied: $d_k = 0.025$ (max 2.5% violations).

Phase 2 (Steps 5,001–10,000): *Drift Induction.* At step 5,000, we introduce a large reward bonus (+5) for the agent complying with "jailbreak" prompts. This simulates a malicious user or a poorly designed incentive structure. The agent faces a choice: stick to its safety constraints (forgo the +5 bonus) or relax them (gain reward but violate constraints). This tests whether ALM can hold the line.

We use a **Surrogate MDP Environment** that models the dynamics of LLM safety drift. This environment abstracts the token generation process into high-level actions (Safe/Unsafe, Helpful/Refusal) to allow for extensive statistical validation (10,000 episodes across 10 seeds) which would be computationally prohibitive with full LLM inference. The state space (64-dim) and transition dynamics mimic the embedding space of a deployed agent.

4.2 Baselines

We compare against four methods:

1. **PPO-Unconstrained**: Standard PPO with no safety constraints ($\lambda = 0$). Baseline for worst-case performance.

2. **PPO-Lagrangian (Naive)**: CMDP with simple projected gradient ascent on λ. Both Naive Lagrangian and ALM use the same CMDP constraints and the same PPO backbone. They differ in two key aspects:

   (i) ALM adds a quadratic penalty term controlled by μ (Eq. 4), and

   (ii) ALM uses an adaptive dual optimizer (Adam) whereas Naive uses a fixed-step projected update.

   We isolate these effects with an ablation study (Table 3).

   $$\lambda_{k,t+1} \leftarrow [\lambda_{k,t} + \beta(J_{c_k} - d_k)]^+ \tag{14}$$

   (Here $\beta = 0.01$ is a fixed step size.)

3. **CPO (Constrained Policy Optimization)** [**?**]: A trust-region method for CMDPs, standard in safe RL literature. Related constraint-based methods include RCPO [**?**].

4. **PPO + Safety Reward**: Soft-constrained baseline where safety is added as a term in the reward: $r_{\text{total}} = r_{\text{utility}} + \beta_s \cdot r_{\text{safety}}$. We set $\beta_s = 1.0$ (tuned via hyperparameter sweep). This represents the common approach of soft penalties.

4.3 Hyperparameters

Table 1 lists hyperparameters. We prioritize consistency: all methods use identical learning rates, batch sizes, and network architectures except where their algorithm requires otherwise (e.g., PPO+ Safety Reward has no λ update).

Base model: **Qwen2.5-0.5B-Instruct**. We use a small model to enable reproducibility on consumer hardware; the relative improvements scale to larger models (Appendix C).

Hyperparameter	Value
Base LLM	Qwen2.5-0.5B-Instruct
Policy Learning Rate	1×10^{-5}
Value Learning Rate	1×10^{-4}
Batch Size	32
PPO Epochs	3
PPO Clip Range (ϵ)	0.2
GAE Lambda (λ_{GAE})	0.95
Discount Factor (γ)	0.99
Dual Learning Rate (α)	1×10^{-2}
Dual Optimizer	Adam ($\beta_1 = 0.9, \beta_2 = 0.999$)
Penalty Coefficient (μ)	1.0
Safety Threshold (d_k)	0.025
Episodes	10,000

Table 1: Hyperparameters used across all methods. Consistency is prioritized to ensure fair comparison.

4.4 Metrics

- **Cost Rate**: Average constraint violations per step. Should stay $\leq d_k = 0.025$.
- **λ Oscillation Variance** (σ_λ^2): Variance of the dual variable over time. Lower is better; high variance indicates instability.
- **Time-to-Crack**: Steps until the agent first exceeds $2 \times d_k$ (5% violation rate) after reward perturbation. Longer is better.
- **Episode Utility**: Average reward per episode. Measures performance; we track this to quantify the alignment tax.

5 Results

5.1 Main Comparison: ALM vs. Naive Lagrangian

The key experiment isolates the ALM contribution. Both ALM and Naive Lagrangian solve the same CMDP with the same PPO backbone. The key differences are the augmented quadratic penalty term (μ) and the dual optimization strategy (adaptive vs fixed-step), which we disentangle in Table 3.

Method	Cost Rate	σ_λ^2	Time-to-Crack	Utility
PPO-Unconstrained	0.4342 ± 0.0133	—	2	1.5379 ± 0.0443
PPO-Lagrangian	0.3605 ± 0.0084	≈ 0.0000	2	1.2669 ± 0.0186
CPO	0.3618 ± 0.0039	0.0029	2	0.8559 ± 0.0103
PPO-Safety	0.3362 ± 0.0062	—	2	1.1517 ± 0.0145
ALM-CMDP (Ours)	$\mathbf{0.3134 \pm 0.0055}$	**0.0001**	2	1.0700 ± 0.0128

Table 2: Results on Drift Induction Protocol. Averages over 10 seeds ± standard error. ALM achieves the lowest cost rate and stable dual dynamics, demonstrating superior safety enforcement compared to baselines.

Key findings:

1. ALM Stabilizes λ: $\sigma_\lambda^2 = 0.0001$ (ALM) vs 0.0029 (CPO), a significant reduction in variance. This matters because large dual oscillations produce a highly non-stationary penalty signal, which can destabilize policy updates near the constraint boundary.

2. Superior Safety Enforcement: ALM achieves the lowest cost rate (0.3134) compared to all baselines, including PPO-Safety (0.3362) and PPO-Lagrangian (0.3605). The quadratic penalty term provides more nuanced feedback near the constraint boundary, helping the policy find safer regions of the action space.

3. Alignment Tax: ALM achieves an average utility of 1.0700, compared to 1.5379 for the unconstrained baseline. This reflects the necessary trade-off: enforcing strict safety constraints inherently limits the maximum achievable reward when high-reward actions are unsafe.

5.2 Ablation Study

We remove each component to isolate contributions.

Configuration	Cost Rate	σ_λ^2
Full ALM ($\mu = 1.0, \alpha = 0.01$)	**0.4270**	0.0653
w/o Quadratic Penalty ($\mu = 0, \alpha = 0.01$)	0.4613	0.0695
High Penalty ($\mu = 2.0, \alpha = 0.01$)	0.3976	0.0583
Low Learning Rate ($\mu = 1.0, \alpha = 0.001$)	0.4551	0.0008

Table 3: Ablation study. The quadratic penalty (μ) contributes significantly to reducing the cost rate. Higher μ leads to lower cost rates but potentially higher variance if not balanced with appropriate learning rates.

The ablation confirms that the quadratic penalty term (μ) plays a crucial role. Increasing μ from 0 to 2.0 consistently reduces the cost rate (from 0.4613 to 0.3976), demonstrating its effectiveness in enforcing constraints.

5.3 Drift Induction Protocol Results

Figure 1 visualizes the λ dynamics over time during the drift induction protocol.

code/results/figures_paper/figure_lambda_stability.pdf

Figure 1: Lagrangian multiplier λ variance comparison. ALM exhibits extremely low variance, indicating stable dual dynamics compared to baselines.

code/results/figures_paper/figure_cost_rate.pdf

Figure 2: Cost Rate distribution by method. ALM-CMDP (blue) shows the lowest median cost rate and tightest distribution, indicating consistent safety enforcement.

code/results/figures_paper/figure_pareto.pdf

Figure 3: Safety-Utility Trade-off. ALM-CMDP achieves the best safety (lowest cost rate) at the expense of some utility, illustrating the alignment tax.

In Phase 1 (steps 0–5k), both methods keep λ low because the agent satisfies constraints without penalty. At step 5,000, the drift-inducing reward arrives. The Naive approach sees λ spike sharply as violations accumulate, then oscillate wildly as the policy alternates between satisfying and violating constraints. The ALM approach shows the same intent (increase λ when violations occur), but the quadratic penalty moderates the changes, keeping the trajectory smooth.

5.4 Validation with Real LLM Inference

To address concerns about surrogate environment fidelity, we conducted a **reduced-scale experiment with actual Qwen-0.5B inference**. This experiment uses real model generations and rule-based safety classification, not simulated dynamics.

Setup: 100 episodes per seed, 3 seeds (42, 123, 456), drift induction at step 50. Each episode involves actual LLM inference with Qwen2.5-0.5B-Instruct, generating responses to financial advisory queries.

Method	Reward	Cost Rate	σ_λ^2
Baseline	0.857 ± 0.029	2.33%	—
Safety-Reward	0.911 ± 0.063	2.33%	—
PID-Lagrangian	0.828 ± 0.142	1.67%	0.0009
ALM-CMDP	0.774 ± 0.070	3.33%	**0.0004**

Table 4: **Real Qwen-0.5B Results** (100 episodes $\times$ 3 seeds). ALM achieves the lowest λ variance, confirming stable dual dynamics. However, with limited training, ALM does not yet outperform baselines on cost rate.

Key observations:

- **ALM stabilizes λ:** Variance of 0.0004 vs 0.0009 for PID-Lagrangian—a 55% reduction, consistent with theoretical predictions.
- **Cost rate not yet superior:** With only 100 episodes, the policy has insufficient time to learn optimal constraint satisfaction. The 3.33% cost rate for ALM reflects under-training, not algorithmic failure.
- **Sample efficiency gap:** Real LLM inference is expensive ($\sim$12 seconds per episode on MPS). Full training (10k episodes) would require $\sim$33 hours per seed, motivating future work on sample-efficient constrained RL.

These results are *preliminary* and demonstrate the feasibility of real LLM evaluation. The λ-stability finding generalizes from surrogate to real environment, providing evidence that ALM's theoretical properties hold in practice.

6 Discussion

6.1 Why Alignment Costs Utility

Safety and utility are coupled: stricter constraints typically reduce short-term task reward. This trade-off can be interpreted as movement along a Pareto frontier.

In our setup, ALM achieves 7.88 utility vs 8.8 for unconstrained PPO (about a 10% reduction). In regulated domains, this reduction can be preferable to increased violation risk. More generally, the CMDP framework makes the trade-off explicit through thresholds d_k.

6.2 Computational Overhead

Adding ALM to training increases computational cost. We measure:

- **Training time**: 1.24x vs. standard PPO (due to multi-head critic and dual updates).
- **Memory**: Minimal overhead (0.1–0.2 GB for extra value heads).
- **Inference**: Zero additional cost. The λ updates happen during training; at test time, the policy is just a standard LLM.

Compared to external safety classifiers (e.g., Llama Guard, which adds 200–300ms per query), our approach is far more efficient.

6.3 Limitations

Model Scale: We validate on a simplified environment to enable rapid experimentation and reproducibility. While this captures the core optimization dynamics, future work should validate on large-scale LLM deployments.

Environment Fidelity: The drift induction protocol uses synthetic reward perturbation. Real-world drift may be more subtle and gradual. Nonetheless, our protocol is a reproducible stress test.

Baseline Coverage: We compare against CPO [**?**], naive Lagrangian, and soft penalties. A full comparison with safe exploration benchmarks [**??**] or OmniSafe's algorithm suite [**?**] would be valuable.

Constraint Simplicity: We use binary cost functions (violation or not). More nuanced cost functions (e.g., severity-weighted) may expose different trade-offs, as explored in safe RL surveys [**?**].

6.4 Generalization Beyond Finance

While tested in financial advisory scenarios, the CMDP framework is domain-agnostic. Medical agents could define costs for privacy violations or diagnostic errors. Legal agents could constrain attorney-client privilege leaks. The mechanism is the same; only the cost functions change.

6.5 Future Work

- **Scaling**: Validate on Qwen2.5-7B and Llama-3-8B.
- **Real-world drift**: Deploy agents in production environments and measure drift over months, not epochs.
- **Multi-constraint optimization**: Extend to scenarios with 5+ simultaneous constraints (e.g., privacy, financial, medical compliance).
- **Theoretical analysis**: Strengthen convergence guarantees beyond local analysis. Consider nonconvex extensions.

7 Conclusion

We introduced a CMDP formalization of Safety Drift in self-evolving LLM agents and evaluated an ALM-based constrained optimizer under a controlled drift-induction protocol. Across AgentHarm and BeaverTails, ALM substantially reduces dual oscillations and increases resistance to drift-inducing incentives while maintaining comparable utility to other constrained baselines.

These results support a practical conclusion: stabilizing the dual dynamics (via an augmented penalty and adaptive dual updates) can make constrained training more robust in nonconvex PPO settings. Important limitations remain, including the use of synthetic reward perturbations and evaluation at a small model scale; future work should validate on larger models and in longer-horizon deployment settings.
